Georgia Grape Horticultural Areas

1. Mountain Area
2. Upper Piedmont Area
3. Lower Piedmont, Middle and South Georgia Area

Three primary species of bunch grapes are grown in the United States: the European bunch grape (*Vitis vinifera*), the American bunch grape (*Vitis labrusca*) and the summer grape (*Vitis aestivalis*). Bunch grapes are often called “pod grapes” in rural Georgia because they produce large clusters of fruit. Georgia’s climate is not well-suited to home garden production of European bunch grapes, but American bunch grapes and hybrids between the two species (French-American hybrids) grow well in Georgia. If grapes are well cared for and sprayed when diseases and insect threaten, you can expect yields of as high as 20 to 30 pounds of fruit per vine. The summer grape is also an American species and is represented by a few varieties good for wine production. If you want to grow European bunch grapes, consult www.smallfruits.org for the *Mid-Atlantic Wine Grape Grower’s Guide*. This is also a good source for more detailed information on growing hybrid bunch grapes. Due to the high fungal disease and insect pressures found in Georgia, the spray program to produce good quality European bunch grapes is intensive and generally impractical for home gardeners.

Pierce’s disease is a bacterial disease spread by leaf-hopper insects that kills susceptible bunch grape varieties. It is very common in middle and south Georgia. Pierce’s disease has not been a significant problem in areas of Georgia above 1,300 feet elevation (high mountain area). Between 1,000 and 1,300 feet (upper Piedmont area), disease pressure varies greatly from site to site, but home garden plantings of Pierce’s disease susceptible bunch grapes are generally feasible. Between 700-1,000 feet in elevation, Pierce’s disease will often destroy the vines of susceptible cultivars within five years. Below 700 feet elevation, Pierce’s disease often destroys the vineyard within three years.

These boundaries can shift with climate variation from year to year. Below 1,000 feet elevation, it is recommended to plant cultivars resistant to Pierce's disease, but incidence of Pierce's disease has recently been reported in vineyards planted as high as 1,500 feet in elevation. Grower and researcher evaluation of relative cultivar tolerance/susceptibility to Pierce's disease is underway in regionally popular hybrid bunch grape varieties.

Best Place to Plant

Late spring frosts can significantly reduce yields across Georgia's Mountain and Piedmont regions, but they can affect southern regions as well. To reduce spring frost risk, it is best to plant grapes on convex rather than concave landforms and on land that is relatively higher in elevation to the surrounding land. This will encourage cold air settling away from vines that have already broken bud. The site should be in full sun most or all of the day. Well-drained, loamy sand, sandy loam, loam or clay loam soils are best for grape production. Soil pHs of 6.0-7.0 are optimal for bunch grape production. Given the high proportion of acidic soils in Georgia, lime amendments are often needed before planting grapevines. Avoid areas where water stands after heavy rains.

Rootstocks

American type bunch grapes and summer grapes are usually grown on their own roots in North Georgia, but some French-American hybrids, such as Traminette, are also own-rooted. European and hybrid bunch grapes are usually grafted on rootstocks such as SO4 or 3309 to provide increased Phylloxera resistance. On sandy sites (especially in South Georgia), test for the presence of root knot nematodes. If they are present, grapes should be grafted on nematode resistant rootstocks such as 'Tampa,' 'Florilush' or 'Dog Ridge.' Low vigor varieties are often grafted to improve their vigor, as noted in the tables. However, some rootstocks, such as Riparia Gloire and 101-14, are used to attenuate the inherent vigor of popularly grown European and hybrid bunch grapes.

Varieties

Many varieties of American type bunch grapes will perform well in Areas 1 and 2 in Georgia. Also, certain selections of French-American hybrid and interspecific hybrid bunch grapes (Traminette, Chardonel, Chambourcin) are suggested for trial in these areas, but these will require more intensive pest management than the American bunch grapes. Hybrid grapes (wine grapes) are suggested for trial in these areas. Several hybrid bunch grapes are worthy of trial in Area 3 of Georgia (See Tables 1 and 2).

Varieties Suggested for Home Garden Trials in Area 3 in Georgia

Several hybrid bunch grape varieties have been developed which are worthy of trial plantings in middle and south Georgia. All of these have good tolerance to

Pierce's disease, the primary limiting factor to bunch grape culture in the middle and southern portion of Georgia. Table 1 lists suggested varieties for home plantings.

Purchasing Plants

Bunch grapes, unlike muscadines, do not require cross-pollination, so it is not necessary to buy two or more varieties for pollination. You may, however, want several varieties to extend the fruiting season. For example, white-berried varieties will often be ready to pick well ahead of red-berried varieties. Most bunch grapes are sold as one-year-old or two-year-old plants that are either grafted or own-rooted. Generally, the two-year-old plants grow better and are worth the small extra investment. Be sure to purchase them from a reliable source.

Planting the Vine and Plant Spacing

It is easiest to construct the trellis before planting, but it can be done after planting. Bunch grapes can be planted anywhere from 6 to 8 feet between vines and 9 to 12 feet between rows; equipment use will primarily dictate between-row spacing. Use straight rows for level or slightly rolling land and contour rows for hilly terrain. Prior to setting the vines, soil test and adjust the soil pH to 6.0-7.0 with the appropriate commercial limestone. However, most Georgia soils are low in magnesium, thus the need for dolomitic limestone.

To plant, prepare a hole large enough to accommodate the entire root system in its natural spread. This can be done with an auger or a spade shovel, but be sure to allow the grapes to expand once planted. If vines are grafted onto a rootstock, trim roots back to approximately 12 inches in length before planting. Set the plant to accommodate for settling, and such that the scion buds are 3 to 4 inches above the soil line; this is particularly important for those grapevines that are grafted onto a rootstock. Fill the hole with the natural topsoil and firm it. **Do not place fertilizer in the hole.** (See section on fertilization.) After firming the soil, water liberally and reduce weed competition, particularly in the first growing season.

Following planting, encourage growth from two to three of the strongest buds. After growth begins, select one or two main trunks from the stronger of these shoots. These will be trained up to the trellis wire that will serve as the fruiting wire. Here, the shoots will be trained out laterally to form the future fruiting cordons.

Trellis Systems and Trellis Construction

Number 9 wire is usually used for grape trellis construction. All posts should be pressure treated or made of termite- and rot-resistant wood such as heart of cedar. Further, the use of steel posts is becoming more popular in vineyards. However, wooden end row structures are usually used in tandem with steel line posts.

American Type Bunch Grapes

American type bunch grapes are vigorous and have a trailing, downward growth habit. However, many hybrid bunch grapes also have a trailing habit and, thus, can be optionally grown on high wire trellising systems as well. Three high trellis systems are commonly used to train home garden American type bunch grapes in the south: the double curtain (two wire horizontal system), the two wire vertical and the single wire. The top wire is typically 5 to 5.5 feet above ground level in all three systems.

Double Curtain Trellis — This trellis system is usually the most desirable of the three systems because of increased yields. The trellis system has two wires 4 feet apart and 5.5 feet above the ground. Figures 1 and 2 show details of how to construct the double curtain trellis. A simple T-bar trellis constructed from treated 4-inch by 4-inch posts can also be used.

Two Wire Vertical Trellis — The two wire vertical trellis used for the four-arm Kniffin training system is considerably less expensive to construct than the double curtain trellis. However, shading of the foliage on the lower fruiting canes by the upper canes reduces the quality and productivity of the grapes on the lower wire. Figure 3 illustrates the construction of the two-wire vertical trellis. The primary use for this trellis is in situations where space is limited, but where there is good direct sun exposure. If direct sun exposure is limited, use the double curtain or single wire trellis.

Single Wire High Trellis — This trellis is recommended where diseases are a problem. Since there is only one set of foliage, the vines dry off more rapidly after a rain on the single wire. While yields are lower compared to the other two high wire trellis systems, the single wire system is easier to manage, requires less trellis construction and supplies, and offers the ability to plant rows closer together than the double curtain system. Construct end supports as shown in Figure 3.

French Hybrid and European Bunch Grapes

Single Wire Low Trellis with Catch Wires (AKA Low Trellis Cordon System) — Most American bunch grapes do not grow upright. However, hybrid and European bunch grapes have new shoots that naturally grow upward. Two removable catch wires above the cordons (arms) further encourage this growth habit and allow good exposure of the fruit to sunlight and fungicide sprays. The low-trellis cordon system establishes the cordons 3 to 3.5 feet above the ground and, depending on post height, includes two to three removable catch wires positioned at 8 to 10 inch intervals above the cordon wire. This system promotes vertical growth, resulting in a narrow, upright vertical canopy (Figure 4). Thus, looking down the row, the tucked upright shoots look like a consistent hedgerow of foliage that is growing above the low-positioned cordon.

Training Young Vines

First Year — Regardless of the training system to be followed, your goal is the development and establishment of a well developed root system. It is recommended that after planting, the strongest cane be cut back to two or three strong buds. Remove any other canes present. Because it is sometimes difficult to determine the condition of a dormant vine, however, some growers prefer to leave five to six buds and then, when growth starts, only allow the most vigorous or desirable buds to develop into shoots. These shoots will be trained to form trunks and cordons, the permanent woody tissues of a grapevine.

If the trellis cannot be constructed the first growing season, then a stake 4 to 5 feet high should be driven in the soil near each vine and the new growth trained to it. Although bamboo can work, it is often unable to stay erect without the support of a wire. Thus, stakes made of stronger materials, such as steel, may be desirable if a trellis is not constructed at the time of planting. Tie the shoots loosely, or with plastic tape, to avoid the possibility of girdling. In cool areas of the country, growth rates are slow and vines are often pruned back to near ground level the first winter to help develop a vigorous trunk the second year. In Georgia, the growing season is long and vines often make impressive growth the first year. While many may opt for training only one trunk, training two trunks provides insurance in case one trunk is subject to mechanical or cold injury.

Double Curtain Trellis — Develop a double trunk (Y-shape) for each vine approximately 30 inches above the ground. This is done by pinching out the growing point and forcing two lateral shoots to develop. One trunk should be allowed to grow to one of the trellis wires and the other trunk to the other wire. Just below the wire, pinch out the tip of the growing shoots to encourage lateral shoot formation and growth. These lateral shoots will be trained to the catch wires to serve as fruiting cordons. Under good conditions, the trunk system for the grape vine should be developed by the end of the first growing season.

Two Wire Vertical Trellis — Develop a single strong shoot arising from the young plant by removing competing shoots. Train this shoot to a string or stake running from the upper wire of the trellis to the ground. Just below each wire pinch out the tip to encourage two lateral shoots to develop. These lateral shoots will be used to train the vine horizontally onto the fruiting wire.

Single Wire Trellis High Trellis and Single Wire Low Trellis with Catch Wires — One shoot should be allowed to develop into the trunk. Train the trunk to a string or a training stake. When the tip reaches the wire, pinch it out and select two shoots growing about eight inches below the wire. Shoots positioned to grow on the trellis wire should be allowed to grow 12 to 18 inches long before they are tied down to the wires. Never tie the

Table 1. Varieties for the Upper Piedmont and Mountains.

Variety	Type	Areas of Georgia	Red Wine	White Wine	Juice Jelly	Fresh Eating	Comments
Venus	I	1 & 2			X	X	seedless, blue-black fruit; seed traces present
Interlaken	F	1 & 2				X	seedless; suffers cold damage often
Foch (Kuhlman)	F	1	X				blue-black fruit
Aurora	F	1		X		X	good wine; fresh eating
Jupiter	I	1 & 2				X	seedless, blue fruit
Reliance	I	1 & 2				X	seedless, red fruit; fruit cracking problems
Cascade	F	1 & 2	X			X	performed well in Georgia test
Van Buren	A	1			X	X	black fruit
Alwood	A	1 & 2			X	X	blue fruit
Ontario	A	1				X	green to amber fruit
Fredonia	A	1 & 2			X	X	blue fruit
Baco Noir (Baco #1)	F	1 & 2	X				blue-black fruit
Delaware †	A	1 & 2	X		X	X	reddish fruit, small but sweet; good red wine
Chelois	F	1 & 2	X				blue-black fruit
Norton (Cynthiana)	A	1 & 2	X				<i>V. aestivalis</i> variety; good quality wine
Chambourcin	F	1 & 2	X				good quality red wine
Mars	I	1 & 2			X	X	seedless, blue fruit
Saturn	I	1 & 2			X	X	seedless, red fruit
Chancellor	F	1 & 2	X				dark red fruit
Buffalo	A	1 & 2			X	X	good yields
Niagara †	A	1 & 2			X	X	golden fruit
Cayuga White	A	1 & 2	X				vigorous vine
Concord	A	1	X		X	X	blue fruit, ripens unevenly; not recommended
Sunbelt	I	1 & 2			X	X	Concord type but ripens more evenly than Concord
Neptune	I	1 & 2			X	X	white seedless
Portland †	I	1 & 2			X	X	amber fruit
Stuben	A	1			X	X	blue fruit
Agawam	A	1			X	X	reddish fruit
Caco	A	1			X	X	reddish fruit
Champagne	A	1 & 2			X	X	reddish fruit
Catawba †	A	1 & 2			X	X	purplish red fruit; uneven ripening
Vidal Blanc	F	1 & 2					yellow-green fruit; well-suited for white wine production
Golden Muscat	F	1			X	X	greenish-amber fruit
Villard Blanc	F	1 & 2		X			greenish-yellow fruit
Seyval Blanc	F	1 & 2		X			yellow-white fruit that can be used to make white wine; may be susceptible to Pierce's disease.
Chardonel	I	1		X			good variety for making white wine
Traminette	I	1		X			good variety for making white wine
Blanc du Bois	A	1 & 2		X			good potential for white wine
Black Spanish (Lenoir)	A	1 & 2	X				dark purple fruit; good potential for red wine production

F/I = French-American or interspecies hybrid; NOTE: hybrids may show varying susceptibility to Pierce's disease; A = American; Some French and interspecific hybrid grapes can have upward-growing shoots and can be grown using a low-trellis design (3 ft.); most American grapes have trailing growth and can be grown using a high-trellis design (5 ft.).

† Should be grafted on Dog Ridge or similar rootstock for best results. There are several Thomas Volney (T.V.) Munson varieties that are good potential bunch grape candidates. A list of these varieties can be found at <https://www.grayson.edu/programs-and-majors/viticulture-and-enology/vineyard/grape-varieties.html>.

Table 2. American Bunch Grape Varieties for Middle and South Georgia.

Variety	Red Wine	White Wine	Juice Jelly	Fresh Eating	Comments
Blanc du Bois		X		X	good potential for white wine production
Orlando seedless				X	small, greenish-yellow fruit
Suwanee		X		X	good eaten fresh and as wine
Stover †		X		X	good, golden fruit
Blue Lake			X	X	purple fruit
Midsouth			X		sour, purple fruit
Miss Blue			X		sour, purple fruit
Conquistador †	X		X	X	very good, similar to Concord
lake Emerald		X		X	greenish fruit
Black Spanish (Lenoir)	X				dark purple fruit; good potential for red wine production.
Daytona †				X	low yield but good eating; pink fruit

† Graft on Tampa, Lake Emerald, Florilush or Dog Ridge rootstock. There are several Thomas Volney (T.V.) Munson varieties that are good potential bunch grape candidates. A list of these varieties can be found at <https://www.grayson.edu/programs-and-majors/viticulture-and-enology/vineyard/grape-varieties.html>.

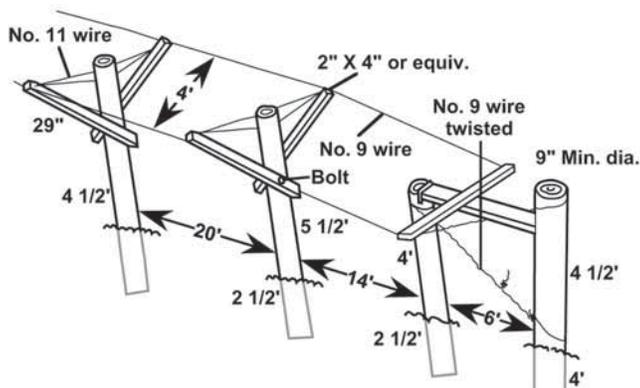

Figure 1. Details for the double curtain trellis.

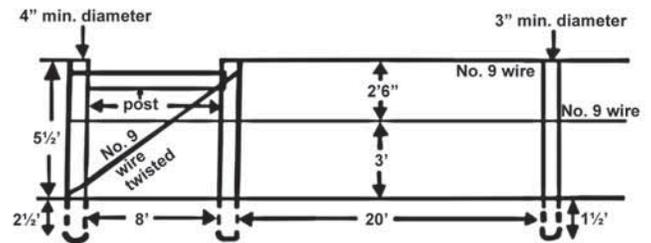

Figure 3. Dimensions of a two wire vertical trellis (4-arm Kniffin), showing end braces.

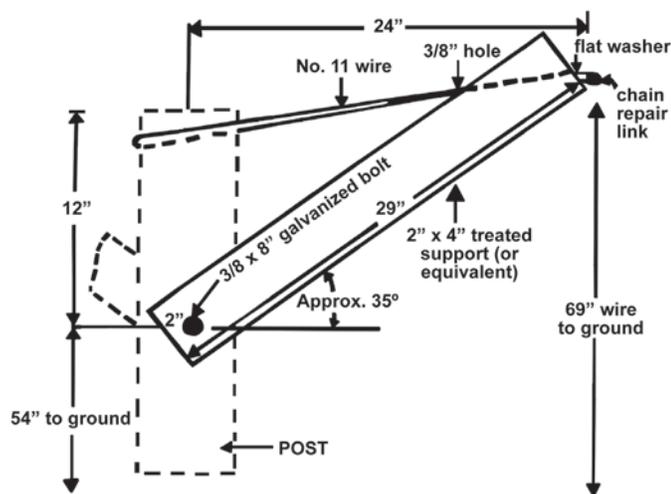

Figure 2. Details of the double curtain support system.

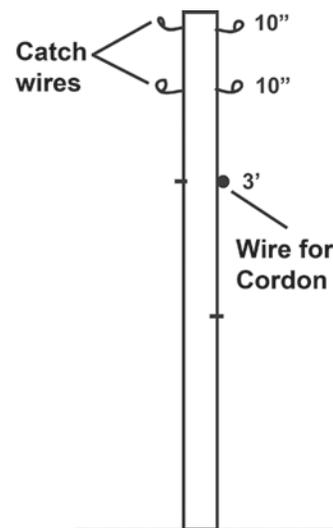

Figure 4. Detail for the single wire low trellis with catch wires. View looking down the row. Special nails or a bend nail can be used for the catch wires.

growing shoot tips to the wire because they will lose vigor. Always leave at least 6 inches of shoot tip free beyond the last tie so it can grow in an upward direction to maintain vigor.

Second Year — The second year should be devoted to training and developing a strong plant structure that can support some fruiting during the third season. Figure 5 illustrates vines properly trained to the double curtain trellis, while Figure 8 illustrates pruning and training to the two wire vertical trellis (Kniffin system).

Assuming normal growth has been obtained during the first growing season, all buds on the trunk remaining after pruning are capable of developing into shoots and producing fruit. Fruit production at this stage of vine development may reduce vegetative growth and, therefore, is not desirable. Thus, removal of flower clusters is recommended in the second year. Exceptions to this rule is if the vine has grown tremendously the first year; in this case, it may be okay to maintain a cluster per shoot. All shoots below the bottom trellis wire should be removed, including suckers from the base of the vine. Continue to develop the permanent cordons (the lateral growth on the fruiting wire).

Pruning the Bearing Vine

Grapes require annual pruning to maintain quality and productivity. Prune during the dormant season which, depending on the zone in which your vineyard is planted, is from late November through late March. Late winter or spring pruning will cause “bleeding” (flow of sap through the pruning wounds), but this should not cause alarm since it does not damage the plant.

Two Types of Training/Pruning: Cordon Training/Spur Pruning and Head Training/Cane Pruning

Two very different types of pruning are used on bunch grapes. While cordon training/spur pruning is by far the most popular training/pruning combination, many vineyard owners also employ head training/cane pruning, particularly in hybrid grapes trained to low trellis systems with vertical shoot positioning. With cane pruning, only the trunk is permanent. The cordons (arms) are formed by leaving several of last year’s canes. With spur pruning, the trunk and the cordons are permanent and the current season’s growth is cut back to short shoots (spurs).

Head Training/Cane Pruning

Do not over crop third year vines. Thin the fruit clusters to one per shoot. Most mature vines (typically 4 years and older) should be pruned to have between 30 and 60 buds. The more vigorous the vine, the more buds should be left. Balanced pruning, a method of pruning to balance production and vine vigor, is recommended for two wire systems. To balance prune, select four canes of last summer’s growth, one for each direction on the two wires. See Figure 7.

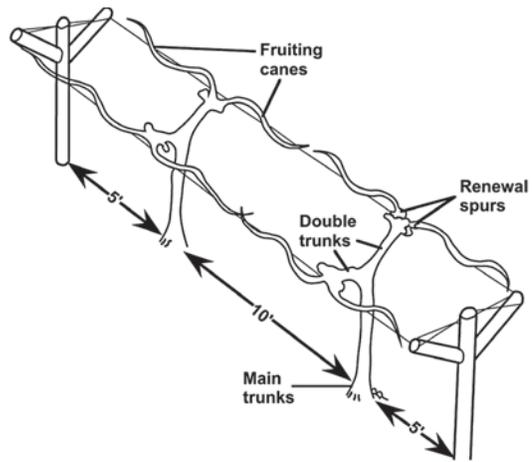

Figure 5. The double curtain trellis showing double trunks, fruiting canes and renewal spurs after pruning.

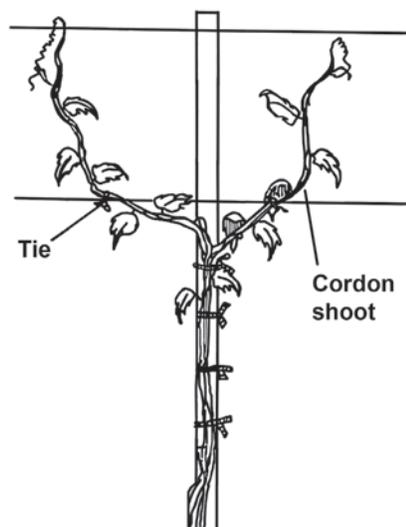

Figure 6. Detail for the single wire low trellis with catch wires. Tie the cordon shoots to the cordon wire only after they are 1.5 to 2 feet long. [From S.C. Master Gardener Training Manual]

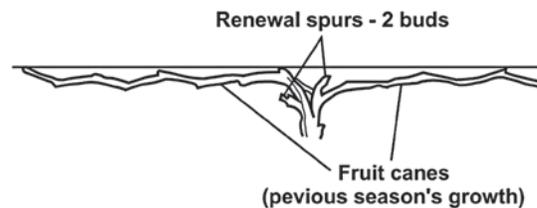

Figure 7. Grape vine properly pruned showing fruiting canes and renewal spurs. Prune each cane on the double curtain or two wire vertical trellis similarly to this.

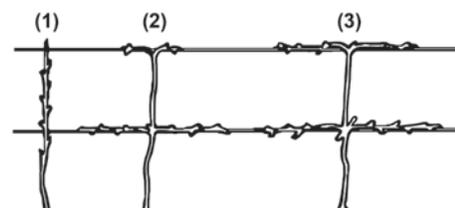

Figure 8. Training the young vine to the two wire vertical trellis (4 arm Kniffin system). 1) Pruning after one year's growth, 2) after two years' growth, 3) after three years' growth.

One benefit to head training/cane pruning is that most shoots that arise from the retained canes are fruitful, and basal/non-fruitful shoots are minimized, thus minimizing the need for shoot thinning to prevent fruit-zone overcrowding. One drawback to head training/cane pruning is that once the canes that will be retained are selected, they must also be tied down to the fruiting wire. These should be selected from canes arising from the head (the region where the vertical trunk “splits” and is trained horizontally to the fruiting wires) of the vine. Canes about the diameter of a pencil are most desirable. Cut each of these back to leave 15 to 20 buds per cane. Gather up all of last season’s canes pruned from the vine and weigh them. **Note: Do not weigh wood that is greater than one year old.** As a rule of thumb, 30 buds should be left on the vine for the first pound of prunings removed, and 10 buds for each additional pound. Vines producing less than .75 pound of prunings should not be cropped. As an example, suppose a vine (after pruning where 60 buds were left) yielded 3.5 pounds of prunings. Then the number of buds to be left would be about 55 (30 for the first pound and 25 for the other 2.5 pounds). Each of the four canes left should be pruned back to have about 14 buds each (14 buds x 4 canes = 56 total buds). If balanced pruning is not to be done, then 30 to 60 buds should be left; the greater number being left on the most vigorous vines.

Leave renewal spurs in the head region to form canes for next year (Figure 7). These spurs are also canes of last season’s growth pruned back to leave only two buds each. From these spurs will grow the fruiting canes for next year. Renewal spurs should be located as near the trunk(s) as possible.

Cordon Training/Spur Pruning

Cordon training/spur pruning is more popular than head training/cane pruning, and this is perhaps due to the ease with which it is executed. It is primarily used on high-wire systems such as the double curtain or single high wire. One drawback to cordon training/spur pruning is that diseases can form in the cordons over time. Further, several basal/non-fruitful shoots can grow from the cordon; as a consequence, the fruit-zone can become overcrowded and more susceptible to fungal diseases due to reduced air movement and fungicide coverage on the fruit. This, however, can be mitigated by selective fruit-zone leaf removal (see below).

Single wire low trellis with catch arms — In late winter, cut back the shoots that grew during the previous summer (now dormant, woody canes). This forms the “spurs.” Leave two to three buds per spur for French hybrid grapes and four to six buds on American type bunch grapes. Select shoots that grew upward in a well-lit environment to have the most fruitful spurs. Remove weak shoots.

In the spring, allow four to six shoots per foot of cordon to develop, removing basal shoots (those arising from

regions other than the one-year-old retained spurs) where necessary. Also selectively remove leaves from around the fruit clusters to improve fruit quality and help reduce disease pressure. These leaves can be removed shortly after bloom but before the berries begin to change color and soften. Do not remove leaves after the berries begin to soften because sunburn may result. Thin fruit clusters to no more than two per shoot. As the new shoots become long enough, place them into the catch wires.

Fertilization

Making soil amendments before planting helps get the young vines off to a good start. As mentioned above, soil pH is critical (6.0-6.5 may be ideal for all grapes) to be sure the vine is getting a balanced supply of macronutrients and micronutrients. If the soil is too acidic (i.e., below 5.5), then the supply of major cations (K, Mg, and Ca) can become out of balance. Contact your county Cooperative Extension agent for assistance with testing the soil prior to planting.

After the plants have been settled by a drenching rain and before growth starts, apply 2 ounces of 10-10-10 fertilizer around each plant. Keep the fertilizer at least 6 inches from the vine and scatter evenly in a circle 2 feet in diameter. This can be repeated, but use your soil test reports and visual observations to gauge the need for further fertilization. Usually, high soil organic matter equals high soil fertility, and the decreased need for repeated fertilizer applications. Remember; these vines are young and are susceptible to nutrient toxicity and tissue burn due to their relatively low plant tissue biomass. Further, most newly planted, young vines show some form of mineral nutrient deficiency because their roots are shallow and in soil profile layers that frequently dry out. Deficiency symptoms are often fixed with a good watering in order to solubilize the nutrients to be taken up by the roots. Perhaps even more important than fertilization is reducing weed competition and making sure the young vines receive ample water supply.

On two-year-old vines, double the first year rate and increase the diameter of the circle to 3 feet. Bearing vines (3 years and older) will need about 2½ pounds of 10-10-10 per plant, and this is best applied around bloom, or flowering. Scatter this evenly under the vines in a band 4 feet wide. Again, use knowledge gained from soil reports as well as visual foliar observations to determine nutrient need. Petiole sampling at bloom is another option to determine vineyard nutrient status, and this can be done annually on commercially mature vines (3 years or older). Information on proper petiole sampling can be found in Extension bulletins by other universities, and plant tissue nutrient analyses can be performed by the UGA Agricultural and Environmental Services Laboratories. Work with your local Extension agent to process plant tissue samples.

Because Georgia soils are inherently low in magnesium, foliar magnesium deficiency frequently

becomes noticeable in mid-summer. This deficiency is characterized by a yellowing between the leaf veins on the older grape leaves. If the soil pH is sufficiently low to warrant liming, use dolomitic lime to help prevent magnesium deficiency in future years; however, liming raises soil pH more effectively when it is incorporated into the soil before planting. Otherwise, magnesium sulfate (epsom salts) should be applied and watered in. It may require 2 to 3 years of magnesium application to bring the level up for the best plant performance.

Cultivation and Weed Control

Make every effort to establish a permanent sod between rows before planting the vineyards to reduce soil erosion. Keep the sod mowed during the summer months. After the sod is established and the vines are planted, hand weeding and hoeing or careful herbicide application will be needed around the individual vines during the first two growing seasons.

Reducing weed competition for soil water and mineral nutrients is imperative for young vines. The use of grow tubes around young vines can offer physical protection from carefully applied herbicides as well as rodents and deer.

Once the vineyard is established and producing fruit (generally the third season), herbicides can be used to

keep the vineyard floor under the vine free of weeds and grasses. Several herbicides cleared for use on grapes do an excellent job if properly used. They can be applied with tractor-mounted or hand-operated equipment, but be sure to remove any green suckers emerging from the trunk and ground before herbicide application. See your county Extension agent for specific weed control recommendations. Mulching is also useful for improving soil temperature and soil moisture and for reducing weed growth.

Insects and Diseases

Since bunch grapes are susceptible to a number of diseases and are attacked by several insect pests, a season-long spray program may be necessary to produce good fruit. Contact your county Extension office for a copy of “Disease and Insect IPM in the Home Orchard.” The publication gives tips for a good spray program along with additional information and precautions. Read and understand the section on precautions first. Pesticides are dangerous when they are misused and mishandled. This and other Cooperative Extension publications are available at extension.uga.edu. Further, please read the “Southeast Regional Bunch Grape Integrated Management Guide,” which can be found online at <http://www.smallfruits.org/SmallFruitsRegGuide/Guides/2016/BunchGrapeSprayGuide2016.pdf>.
